'Environmental mastitis' refers to intramammary infections caused by organisms that survive in the cow's surroundings – including in soil, manure, bedding, calving pads, water, or on body sites of the cow other than the mammary gland. Infection of the udder with these organisms is often opportunistic, taking advantage of circumstances that favour environmental contamination and changes in the mammary gland's susceptibility to infection. There are many bacteria in the environment and some have biological characteristics that enable them to multiply within the udder.

Most cases of environmental mastitis occur within a few weeks of calving, when the cows' natural defence mechanisms are low and their udders have been in contact with mud and manure during calving. However, exposure of teat ends to environmental bacteria can occur at any time: before heifers have their first calf, during calving, at milking time or in paddocks during the lactation or dry periods. During lactation, factors that predispose cows to infection with environmental bacteria include milking udders that are wet or dirty, or administering intramammary infusions if the teat orifice is not sterile. During the early and late dry periods, absence of the keratin plug in the teat canal may make cows highly susceptible to infection.

Bacteria that commonly cause environmental mastitis are Streptococcus uberis or Escherichia coli. Other environmental organisms causing mastitis include other coliform bacteria (Klebsiella species, Enterobacter aerogenes), Pseudomonas aeruginosa, Bacillus cereus, Arcanobacterium (formerly Actinomyces or Corynebacterium) pyogenes, Serratia species, Nocardia species, Candida (yeast) and Protheca (algae). Characteristics of some of these bacteria are described in the following tables.

Strep uberis usually responds to treatment but some cases can be difficult to cure. Coliforms do much of their damage through toxins released after the bacteria die. Pseudomonas is virtually impossible to treat and cows that survive must be culled.

Streptococcus dysgalactiae has characteristics of environmental and cow-associated causes of mastitis and it is not easy to categorise. In Australia, Strep dysgalactiae is commonly seen in heifers before they start lactation. The bacteria can be isolated from the environment and from sites on the animal such as the mouth, udder and vagina. Infection can occur between milking from Strep dysgalactiae in the cow's environment or it may be spread between cows at milking. Flies can physically spread the bacteria.

Technote 14.3 and 14.4 discuss Strep uberis and blanket Dry Cow Treatment.

Technote 5 describes characteristics of common cow-associated mastitis bacteria.

### Bacterial shedding in milk

- **Cow susceptibility**: Infection most frequently occurs in the first two weeks of the dry period, and during the calving period and early lactation, especially if there is teat end damage or oedema. In the early dry and calving periods, changes in udder secretions, the lack of flushing at milking, and the absence of the keratin plug in the teat canal make the cows highly susceptible to infection. Infection with Corynebacterium bovis may make quarters more susceptible to Strep uberis (Hogan et al 1988).

- **Clinical signs**: About 50% of clinical cases have an enlarged, inflamed quarter and changes in the milk. In about 40% of cases changes are visible only in the milk. In about 10% of cases the cows develop a fever and go off their feed. Research indicates significant differences between the ability of various strains of the bacteria to infect the udder. Some strains are protected by bacterial capsules, some invade mammary tissue and may resist natural defence mechanisms and the action of antibiotics.

- **Bacterial shedding in milk**: The bacteria can be isolated from the environment, faeces and many sites on cows – especially the abdominal skin. Some cows pass large numbers in their faeces. The udders of chronic, subclinically infected cows are a potential reservoir and their milk may contaminate milking equipment.
**Characteristic** | **Strep uberis** | **Escherichia coli**
--- | --- | ---
Most infections are short-lived but a small percentage become chronic (Hogan and Smith 1997). | Bacteria are shed in the first 6-12 hours of clinical signs, and are reduced thereafter. | Most infections are of short duration – more than 50% last less than 10 days. Some (1-2%) continue for more than 100 days. | Severe cases are nearly always culture positive. Other cases are often culture negative because the cows have already eliminated the bacteria.

**Cell counts (ICCC)**
Most infected cows have ICCC higher than 500,000 cells/mL. | ICCC rapidly increase following infection and persist for about two weeks, after which the bacteria are eliminated. | In chronic cases ICCC tend to be high (about 500,000 cells/mL) although they can fluctuate.

**Milk quality**
Bacteria are not usually found in vat milk unless there is a high prevalence of infection in the herd. | Clinical and chronic coliform cases do not contribute significantly to vat milk contamination. | Most isolations from vats are likely to be from bacteria on teat surfaces rather than from udder infections. | Most isolations from vats are likely to be from bacteria on teat surfaces rather than from udder infections.

**Management during outbreaks**
Manage calving cows to minimise exposure to contamination. If possible, use sand rather than organic materials for calving pads. | Manage calving cows to minimise exposure to contamination. Begin milking and disinfecting teats of cows tight with milk prior to calving, especially those leaking milk. | Begin milking and disinfecting teats of cows tight with milk prior to calving, especially those leaking milk. | Improve pre-milking hygiene and consider pre-dipping teats before milking. | Improve pre-milking hygiene and consider pre-dipping teats before milking.

Examine milking machine functions (especially pulsation, liner length and vacuum). | Overseas, vaccination with J-5 vaccine in the dry and early lactational periods reduces the incidence and severity of many of the coliform infections. This vaccine is not registered for use in Australia. | Use blanket long-acting Dry Cow Treatment at the next dry period to prevent new infections.

*Escherichia coli infection is often called ‘coliform mastitis’, which can also be caused by the less common but related bacteria Klebsiella spp and Enterobacter aerogenes.*

Confidence – High
Local observations of the importance of hygiene in calving areas are consistent with overseas research and experience.

Research priority – Moderate
Further information on what constitutes a successful calving pad surface, including measurement of pathogen counts, could be useful.

If possible heifers should be calved separately from the adult herd. Heifers are more likely to be bullied and be forced to calve in the less suitable areas of the calving paddock or calving pad.

1.1 Calve on clean, dry pasture or a clean, dry calving pad.

The udder is very susceptible to infection at calving, and many infections detected in early lactation are established at calving (Hogan and Smith 1998).

The ideal place for cows to calve is a clean, sheltered, dry area. The ideal situation is a paddock with a good cover of grass, not irrigated or contaminated with milking shed or feed pad effluent, on an elevated site that is not wet, boggy or poorly-drained. Unfortunately, such areas are rare on most Australian dairy farms and most farm managers choose to use calving paddocks where the cows can easily be supervised or calving pads, especially in areas of high rainfall during the calving period.

Calving paddocks can work if they are large enough so that grass cover is maintained. However, it is common for small areas, which perhaps provide shelter, to be overused and become boggy. The only practical solution is to fence off such areas until they regenerate. If electric fences are shifted across a paddock at regular intervals, clean areas can be provided for new batches of calving cows. It is important to avoid ‘back-grazing’ (where cows have access to recently contaminated areas in addition to their new area). Some planning is needed to create access lanes and allow for access to drinking water in each strip-grazing area, for example by using mobile troughs. When cows are calving on grass it is also important to ensure that preventative measures for metabolic diseases have been taken.

Calving pads can be a successful alternative for wet conditions. Drainage is probably the most important factor and can be supplied by providing sufficient fall on the pad (of about 3-4%), or by installing underground slotted polyvinyl chloride (PVC) pipe drainage on flat sites (Davison and Andrews 1997).

Usually some bedding material is provided to make the cows more comfortable. Organic bedding materials (straw, rice hulls, shavings or sawdust) support higher bacterial populations than non-organic materials (washed sand or ground limestone). The particle size is also important. The surface area for bacterial growth and the chance of bacterial attachment and colonisation is increased in finely chopped or ground organic material. For this reason, long straw is generally better than finely chopped straw and shavings are better than sawdust (Hogan and Smith 1998).

Sawdust and other wood products tend to harbour the coliform bacteria and straw may contain large numbers of environmental streptococci, such as Strep uberis (Bramley 1982, Smith and Hogan 1997). Sawdust may have high pathogen (Klebsiella species) counts even when fresh (Hogan et al 1989). Kiln-dried sawdust is less of a problem. Sawdust can be used satisfactorily provided it is stored dry and managed correctly (Blowey and Edmonson 1995). Pathogen counts are much lower when contaminated sawdust is removed and replaced with fresh sawdust daily rather than weekly (Bramley 1992). Sawdust should not be used as bedding if it cannot be kept dry.
All bedding materials (organic and inorganic) will support high pathogen counts after becoming contaminated with manure (Blowey and Edmonson 1995). The area must be kept well drained and contaminated material removed and replaced on a regular basis. Pathogen counts will be high before the bedding looks soiled, and chemical disinfection (agricultural or hydrated lime, formalin, etc) of contaminated bedding is not effective (Hogan and Smith 1998).

The recommendations that no more than two pats of manure are present per square metre and no water is visible in footprints are crude estimates designed to focus farmers’ attention at least on gross contamination, given the lack of other more sophisticated monitoring techniques. Checking for fresh liquid manure, rather than dried pats, gives an indication of recent faecal contamination.

Practical and economic factors influence the surfaces available for calving cows and must be individually assessed for each farm.
1.2 Be alert to the number of cases of mastitis occurring, especially in freshly calved heifers. This is an indicator of the state of the paddock.

Mastitis in freshly calved heifers (first calvers) may result from infection that has occurred during their development since puberty or in the few weeks immediately before calving.

Heifers may be particularly susceptible to infection during the calving period. This is because they tend to spend longer calving, especially on the ground, and they often suffer from some degree of udder oedema that may reduce the ability of the teat and udder tissues to resist bacterial challenge (Slettbakk et al 1995). Field observations indicate a greater tendency of animals with oedematous teats to develop Strep uberis infections.

Clinical mastitis was observed at calving in 8% of first-calf heifers in a study of 11 herds in New Zealand (Pankey et al 1996). Environmental streptococci were isolated from 68% of these clinical cases.

The warning index of three or more cases in the last 50 calvings is an estimate based on the average incidence of clinical cases observed in the first month of lactation. Data on the incidence during the calving period (two weeks before and two weeks after calving) would allow this index to be refined, but it serves as a reasonable guide. It is probably of more relevance in seasonal herds where relatively large numbers of calvings occur over a short period (and 50 calvings may occur in as little as 1-2 days).

If this index is exceeded a reassessment of the calving environment and management should be made. It is often useful to have an independent adviser help with this to obtain the benefit of a ‘fresh pair of eyes’. It is also worth noting that sometimes a high incidence of mastitis occurs at calving, even though the environment appears clean and dry. These may be infections that occurred at an earlier time (for example at drying-off) and then became clinical at calving.
1.3 Bring cows into the shed as soon as possible to milk out and check – certainly within 24 hours of calving.

In 1996 Pankey et al noted that many ‘over-conditioned’ heifers leaked milk prior to calving and had a higher prevalence of mastitis. They believed preferential treatment of heifers during the calving period may reduce the incidence of new infections and suggested several factors to aid mastitis control in heifers including:
- minimising exposure to muddy conditions;
- milking them out as soon as possible after calving; and
- applying an effective teat sanitiser after every milking.

In the past, preventive management of milk fever (a sudden reduction in the calcium level in the blood) sometimes involved leaving milk in the udder of fresh cows. This practice is now discredited because it predisposes to mastitis (O’Shea 1987). Rather than treating milk fever by incomplete milking, it should be controlled by managing the diet before and at calving to manipulate calcium availability in this period.
**1.4 Take special care with induced cows.**

Long-acting corticosteroids (such as dexamethasone) are widely used to induce parturition in dairy cattle in parts of Australia. They can impair secretion of proteins that are critical to normal cellular and humoral immune responses (Nonnecke et al 1997), an effect that is strongly linked with changes in the composition of the white blood cells. The ability of cows to respond to stressors may be reduced by the use of long-acting corticosteroids to induce premature calving.

Browning et al (1990) describe a collapse syndrome associated with the use of dexamethasone for inducing calving. It appeared to result from gram-negative endotoxaemia associated with subclinical infections as three of the seven cows in this study had peracute Escherichia coli mastitis confirmed at post-mortem examination.

Immune suppression resulting from the use of long-acting corticosteroids to induce parturition is still profound at the time of parturition. Steps must be taken to minimise exposure of induced cows to mastitis-causing pathogens at this time.

To minimise the risk of environmental mastitis in induced cows, practitioners recommend the following procedures:

- Maintain cows in clean, well-drained paddocks (the best calving area available on the farm) from the time they receive their first injection to induce parturition until after they have calved.
- Milk cows once the udder is tight with milk. Induced cows often bag-up tightly before calving and may drip milk. Machine milking is recommended once the udder gets tight with milk, even though the cow may not yet have calved. “If she’s dripping milk, she should be milking.”
- Watch udders carefully for signs of mastitis. Some cases can be rapid and severe with few initial changes or abnormalities in the milk (e.g. water milk, clots or flecks).
- Monitor induced cows very closely for signs of systemic illness. Cows may become acutely ill with an *Escherichia coli* mastitis endotoxaemia, even though visible changes in the udder may be limited and the secretion from the affected quarter is difficult to differentiate from colostrum.
1.5 Take care with pre-milking preparation of udders.

Technote 5 describes good milking technique and the importance of consistent routine.
